Light Scattering, Electrophoresis, and Turbidimetry Studies
of Bovine Serum Albumin–Poly(dimethylallylammonium
chloride) Complex

Received December 21, 1992. In Final Form: May 13, 1993

Complexation between bovine serum albumin (BSA) and poly(dimethylallylammonium chloride)
(PDMDAAC) was studied by static and quasi-elastic light scattering (QELS), electrophoretic light scattering,
and turbidimetric titration in dilute electrolyte solution. Both QELS and turbidimetric titration show
that complexation occurs at pH > 4.6. The structure of the BSA–PDMDAAC complex in excess protein
solution at ionic strength 0.01 M and pH 7.88 depends on the polymer concentration. At low polymer
concentration, an intrapolymer complex saturated with BSA is formed. This intrapolymer complex
aggregates to interpolymer species upon increase in the polymer concentration.

Introduction

Protein–polyelectrolyte complexes (PPCs) can play an important role in a variety of chemical and biological
processes, such as protein separation,1-3 enzyme stabilization,4,5 and polymer drug delivery.6,7 Also, by studying
PPC formation we may improve our understanding of interactions between proteins and nucleic acid in the
transcription process.8 The nature of the polyelectrolytes and proteins comprising the complexes controls their
chemical and biological properties, as well as their composition, structure, and size. Therefore, molecular weight
(MW) and size measurements of PPCs are particularly important since both composition and structure can be
deduced from these measurements. However, MW measurement is difficult. The concentration dependence of
PPC structure obstructs the classical analysis of light scattering data by, e.g., Zimm plots. The same effect
interferes with size exclusion gel permeation chromatography because the sample under study undergoes
substantial dilution during the measurement process, leading to PPC dissociation or structure change.

Recently, Dautzenberg et al.9 reported on the static light scattering of complexes formed from the enzyme invertase
and a polycation. A similar study on antigen–antibody complex was carried out by Yarmush et al.10 These
measurements are successful due to the following reason: all the complexes were studied under conditions of excess
protein so that the solution contains only complex and free protein. Since the scattering intensity from the former

Sample Preparation. All solutions were prepared by mixing dust-free (filtered by Gelman 0.2 μm syringe filters) stock solutions of the individual components. The concentration of BSA was 0.5 g/L, and pH was kept at 7.88 in 0.01 M phosphate buffer. Solutions for type I titration were prepared in 0.01 M NaCl instead of phosphate buffer in order to maintain constant ionic strength.

Quasi-Elastic Light Scattering (QELS). QELS measurements were made at scattering angles from 30° to 160° with a Brookhaven (Holtsville, NY) 72-channel BI-2030 AT digital correlator and using a Jodon 15-mW He–Ne laser (Anser, AR). A 200-μm pinhole aperture was used for the EMI photomultiplier tube, and deacydroxynaphthalene (decalin) was used as the refractive index matching fluid to reduce stray light. We obtain the homodyne intensity—intensity correlation function $G(q,t)$, with $q$, the amplitude of the scattering vector, given by $q = (4πn/λ) \sin(θ/2)$, where $n$ is the refractive index of the medium, $λ$ is the wavelength of the excitation light in a vacuum, and θ is the scattering angle. For a Gaussian distribution of intensity profile of the scattered light, $G(q,t)$ is related to the electric field correlation function $g(q,t)$ by

$$ g(q,t) = A(1 + bg(q,t)^2) $$

where $A$ is the experimental baseline and $b$ is a constant, which depends on the number of coherence areas that generates the signal ($0 < b < 1$). The quality of the measurements was verified by determining that the difference between the measured value of $A$ and the calculated one was less than 1%. The electric field correlation function depends on the Fourier transform of the fluctuating number density of particles or molecules. For the center of mass diffusion of identical particles, the following simple relation holds

$$ g(q,t) = e^{-q^2/2} $$

where $r$ is decay time and $D$ is diffusion coefficient. More detailed discussions of QELS data analysis may be found in refs 16 and 17.

For polydisperse systems the correlation function $g(q,t)$ can be expressed as an integral of the exponential decay functions over the distribution of relaxation times $ρ(τ)$

$$ g(t) = \int \rho(τ) e^{-q^2/2} dτ $$

In principle, it is possible to obtain the distribution $ρ(τ)$ by integral transformation of the experimental $G(q,t)/A - 1^{1/2}$, but in practice this presents a formidable problem for numerical analysis, since taking the inverse Laplace transform is numerically an ill-posed problem. Several numerical methods developed so far are devoted to calculating $ρ(τ)$. In the present work, we analyze the autocorrelation functions by using the CONTIN program, which employs the constrained regularization method.18

From eq 3, the mean relaxation time, $⟨τ⟩$, defined as the area of $g(t)$, is given by

$$ ⟨τ⟩ = \int g(τ) dτ = \int ρ(τ) dτ/\int ρ(τ) dτ $$

This $⟨τ⟩$ value can be resolved from each of the distribution modes of $ρ(τ)$, as the first moment of the normalized relaxation spectrum. Therefore, the diffusion coefficient, which corresponds to each value of $⟨τ⟩$, can be calculated using

$$ D = \frac{λ^2}{16π^2 sin^2(θ/2)} $$. (5)

From each $D$ value we obtain Stokes' radius, $R_s$, by the Einstein equation

$$ R_s = \frac{kT}{6πND} $$

where $k$ is Boltzmann's constant, $T$ is the absolute temperature, and $N$ is the viscosity of the solvent.

Static Light Scattering (SLS). SLS measurements were made with the same Brookhaven system described above. Intensity measurements were calibrated by pure (>99.5%) toluene and optical alignment was ensured by less than 3% deviation from linearity in the light vs θ plot. Each measurement was carried out for 5 s. The average of 10 such measurements was reported as $I_r$. These values were used to calculate Rayleigh ratio, $R_s$.

To determine the molecular parameters of a macromolecule, static light scattering results are usually plotted as Zimm diagrams corresponding to the equation

$$ \frac{Kc}{R_g} = \frac{1 + 16π^2 R_g^2 sin^2(θ/2)}{3} + 2A_2c $$

where $c$ is the mass concentration of polymer, $K$ is a constant which contains the optical parameters of the system, $M_g$ and $R_g$ are the weight average molecular weight and the root mean square radius of gyration of the macromolecule, respectively, and $A_2$ is the second virial coefficient.

Electrophoretic Light Scattering (ELS). ELS measurements were made at four scattering angles (8.6°, 17.1°, 25.6°, and 34.2°), using a Coulter (Hialeah, FL) DELSA 440 apparatus. The electric field was applied at a constant current of 5 mA.

In ELS, the photon-counting heterodyne correlation function for a solution with an electrophoretically monodisperse solute can be written as

$$ C(τ) = β_0δ(τ) + α_0 + α_1 \exp(-2Dq^2τ) + α_2 \exp(-Dq^2τ) \cos(Δωτ) $$

where $β_0$, $α_0$, $α_1$, and $α_2$ are constants independent of correlation time, $τ$, and $δ(r)$ is the delta function. $D$ and $q$ have the same definitions as in QELS. The cosine term is due to simultaneous electrophoresis and diffusion.

The Fourier transform of eq 9 with respect to time, as stipulated by the Wiener–Khinchine theorem, gives the power spectrum

Results and Discussion

1. BSA-PDMDAAC Complexation at Varying pH and Mass Ratio. Figure 1 shows the type 1 turbidimetric titration curves of PDMDAAC at various concentrations in 0.60 g/L BSA solution, at ionic strength (I) of 0.01 M NaCl. All of the curves display an abrupt increase in turbidity at pH 5.1, about 0.2 pH unit above the isoelectric point of BSA, corresponding to colloidal complex formation. Prior to colloid formation, we observe a ~2% turbidity increase at pH 4.6 for all polymer concentrations. This small turbidity increase is due to the initial formation of the soluble complex: particles with a size larger than either BSA or PDMDAAC are detected at this pH by QELS, as shown in Figure 2. All solutions exhibit turbidity maxima at ca. pH 6.4. These turbidity maxima can be understood from the simultaneous effects of increasing complex size and solubility. It is well-known that protein-polyelectrolyte complexation is a result of electrostatic interactions. Therefore, increasing the negative net charge of BSA via increase in pH will enhance its binding to polymer, leading initially to a loss of solubility. After the polymer is saturated with bound BSA, the solubility of the complex may increase with pH because the whole polymer chain is covered by the highly charged proteins. The competition of these size and solubility effects causes the maxima in turbidity.

Figure 2 shows the diameters obtained by QELS for the BSA-PDMDAAC complex as a function of pH for complexes formed at r = 10 and 300, respectively. Clearly, size increases with pH after initial binding in both cases. However, the complex at r = 300 shows a constant diameter of ca. 270 nm at pH > 5.80, while the solution at lower r becomes too turbid to measure. The limited size of the complex in the presence of excess protein supports the hypothesis advanced above that the saturated complex may resist higher aggregation.

2. Static Light Scattering of BSA-PDMDAAC Complex. Prior to static light scattering, the degree of complexation was first estimated by the following procedure. A model solution with pH 7.88 and ionic strength 0.01, with r = 300 of BSA and PDMDAAC was centrifuged and filtered through a 20-nm filter. The solution obtained was found to be complex-free by QELS. The concentration of free BSA in the solution was then determined by optical density measurement at 280 nm using the reported extinction coefficient of 4.36 × 10^4. From the free BSA concentration, we obtained β = C_{BSA}/C_p = 39, which corresponds to 120 BSA bound per PDMDAAC chain.

Static light scattering results obtained for the complex with r = 300 in 0.01 M phosphate buffer at pH 7.88 are shown in Figure 3. The refractive index increment of the complex was calculated from eq 7 with β = 40. To analyze the SLS results, we ignore the particle interaction term, i.e., the second virial coefficient in eq 8. The error caused by this approximation is less than 5% because of the

very low polymer concentration. Therefore, eq 8 can be simplified to

$$
\frac{Kc_\text{r}}{R_g} = \frac{1}{M_x} \left( 1 + \frac{16\pi^2}{3\lambda^2} R_g^2 \sin^2 \frac{\theta}{2} \right)
$$

(12)

where \( c_r \) and \( M_x \) are the concentration and molecular weight of the complex, respectively. \( c_r \) and \( M_x \) are related to the polymer concentration and polymer molecular weight by

$$
c_r = c_p (1 + \beta)
$$

(13)

$$
M_x = M_p aM_p (1 + \beta)
$$

(14)

where \( a \) is the degree of aggregation, i.e. number of polymer chains within one complex. Substitution of eqs 13 and 14 into eq 12 yields

$$
\frac{Kc_\text{r}}{R_g} = \frac{1}{\alpha M_p (1 + \beta)} \left( 1 + \frac{16\pi^2}{3\lambda^2} R_g^2 \sin^2 \frac{\theta}{2} \right)
$$

(15)

Therefore, we may use the known polymer concentration \( C_p \) to evaluate the molecular weight of the complex by plotting the angular dependence of the scattered intensity as \( Kc_\text{r}/R_g \) vs \( \sin^2(\theta/2) \) as shown in Figure 3. Such results are plotted in Figure 4 as \( M_x \) vs \( C_p \). The constant molecular weight at low polymer concentration of \( M_x = 8.1 \times 10^8 \) corresponds to a \( \beta \) value of 40 ± 2, which is consistent with the value obtained by filtration. This initially constant \( \beta \) also supports the proposed intrapolymer complex structure.

The radius of gyration of the complex may be obtained from the slope of Figure 3. For different amounts of added polymer, values of \( R_g \) and corresponding hydrodynamic radii, obtained from QELS, as well as \( \rho = R_g/R_h \), are given in Table I. Hydrodynamic theory\(^{28}\) shows that \( \rho \) changes from infinity to 0.775 when the polymer structure changes from a long rod to a sphere. For a random coil structure,

$$
\rho \approx 26.4 - 6.0pH
$$

(17)

From eqs 16 and 17 the mobility is expected to be linear with pH at \( 6 < pH < 10 \), as observed, if the friction coefficient of complex \( f_s \) is independent of pH. This result is consistent with a saturated state of the complex (i.e. \( n \)

\(^{27}\) Xia, J.; Dubin, P. Unpublished results.

\(^{28}\) Tanford, C. J. Am. Chem. Soc. 1959, 72, 441.
this titration) and after bind phosphate the sequence is identical along the same to each other. Under these conditions, these observation suggests A is not found in the supernatant solution; Δ is from the direct measurements of the complex solution.

is constant). Substituting eq 17 and \( n = 120 \) obtained by SLS into eq 16, we obtain \( f_p = 3.2 \times 10^{-3} \) cm, which is much larger than that obtained by the Einstein equation:

\[
f = 6 \pi \eta R = 2.4 \times 10^{-3} \text{ cm}
\]

The unrealistic value obtained for \( f_p \) may arise from several sources. First, the Einstein relationship is not expected to hold in the present case because of hydrodynamic and electrostatic interactions. A second weakness in the preceding analysis is the neglect of counterion condensation. Nevertheless, the approach embodied in eq 16-17 accounts in the simplest way for observed linear dependence of \( u \) on pH.

4. Size and Mobility of BSA–PDMDAAC Primary Intrapolymer Complex. Figure 6 shows the diameter of the BSA–PDMDAAC complex formed in 0.01 M pH 7.88 phosphate buffer and BSA concentration of 0.6 g/L as a function of the polymer concentration, \( C_p \). The triangles represent data obtained by QELS directly on the solution. The circles are from measurements on the supernatant of the solution after 20 min of centrifugation at 10,000 rpm. Up to a polymer concentration of \( C_p = 0.15 \text{ g/L} \), the species formed consistently exhibits a diameter of 190 nm, which is identical to the value obtained from all supernatants. The same value of \( C_p \) corresponds to the onset of a plateau in the electrophoretic mobility, as shown in Figure 7. Below this concentration, the mobility exhibits a sign change after displaying a constant value of \( u = -1.4 \) (\( \mu \text{ cm} / \text{V s} \)) in the range 0 < \( C_p < 0.05 \text{ g/L} \). These observations suggest the presence of a primary (intrapolymer) complex at low \( C_p \). Under these conditions, the large excess of protein, along with the strong intrinsic binding that is a consequence of the large negative protein charge (–21 by titration) and low ionic strength, ensures the saturation of each polymer chain. There is essentially no free polymer in these systems at low \( C_p \), only intrapolymer complex and free protein. We estimate that each polymer may bind on the order of 120 protein molecules, corresponding to a net protein charge in excess of –1900. Consequently, the primary complex has a net negative charge and hence a negative mobility, i.e. –1.4 (\( \mu \text{ cm} / \text{V s} \)), as shown in Figure 7. Intrapolymer repulsion among the bound protein molecules causes the chain to expand, with a hydrodynamic radius approximately 4 times larger than the value of the protein-free polymer (\( R_b = 24 \text{ nm} \)). The net negative charge of this complex precludes higher-order association. After sufficient polymer has been added to bind all the free protein, further addition of the polycation leads to flocculation of the primary complexes. Since more than one polymer chain is involved in the flocculation, very large particles of interpolymer complex are observed, as shown in Figure 6 at \( C_p > 0.15 \text{ g/L} \). From electrophoretic light scattering, as shown in Figure 7, we also find the mobility of the complex changing to positive, consistent with multipolymer complex formation. Figure 6 also shows the size obtained for particles after centrifugation. The fact that particle size in the supernatant is the same as the size of the “primary” intrapolymer complex at low \( C_p \) suggests that the primary complex is in equilibrium with the separated phase.

Conclusions

The structure of the BSA–PDMDAAC complex in solutions of \( C_p = 0.6, f = 0.01 \text{ M} \), and pH 7.88 depends on the polymer concentration. At low polymer concentration, an intrapolymer complex is saturated with BSA. The mass ratio of the bound BSA to polymer in the saturation limit is about 40. This intrapolymer complex aggregates to interpolymer species upon increase in the polymer concentration. The successful application of static light scattering to a complex with unknown concentration could make this technique useful for a variety of systems, including antigen–antibody complexes used in clinical diagnostics.
